Maximizing early learning

The Explorer Mini is a power mobility solution designed to aid in the achievement of developmental milestones by introducing self-initiated movement for children with mobility impairments at an earlier age.

Importance of early mobility on development

- “The positive impact of power mobility use on overall development in very young children has been supported by a randomized controlled trial [Jones, McEwen, & Neas, 2012] as well as case-studies [Jones, McEwen & Hansen, 2003; Lynch, Ryu, Agrawal, & Alloway, 2009]. In contrast, for older children, there was no change in intelligence quotient (IQ) after six months of power wheelchair use [Bottos et al., 2001]."
- “For outcomes related to body structure and function, strong evidence from a smaller number of studies support positive impact on overall development” (p. 959).

- “In order to limit the impact of physical disability on overall development, clinicians should consider augmenting independent mobility opportunities around the same age as children typically begin to crawl” (p. 218).
- “With access to a specialized power mobility device, it is possible for infants with disabilities to have augmented mobility experiences as early as 8 months of age” (p. 218).
- “For children with minimal mobility experience, a power mobility device can promote overall development as well as functional mobility” (p. 218).
- “Many children with severe intellectual and/or sensory impairments can learn to use a power mobility device competently with appropriate practice and environmental support” (p. 219).

### Early mobility and cognition

<table>
<thead>
<tr>
<th>Study</th>
<th>Description</th>

</thead>
</table>
- Study completed with 20-month-old with SMA: “Within 6 weeks after receiving the power wheelchair, the child operated the wheelchair independently. She showed developmental gains in all domains of the Battelle Developmental Inventory [communication, personal-social, and cognition] and the Pediatric Evaluation of Disability Inventory [positive trends in self-care, mobility, and social function] over 6 months” (p. 253). The authors conclude that the power mobility may have been associated with these changes. |
- During training period from age 7 months to 12 months, “the infant improved in all driving variables. The infant’s Bayley III cognition and language scores also increased at a rate greater than his chronological age” (p. 362). |
- “Twenty-six children with physical disabilities between the ages of 20 and 36 months were evaluated on the cognitive assessment and participated in the wheelchair training and assessment program. A stepwise regression analysis was used to determine which of the cognitive skills predicted wheelchair mobility performance. The cognitive domains of spatial relations and problem solving were found to be significant and accounted for 57% of the variance in wheelchair skills” (p. 665). |

### Early mobility and communication

<table>
<thead>
<tr>
<th>Study</th>
<th>Description</th>
</tr>
</thead>
</table>
- Case report of 21-month-old with cerebral palsy. During 12-week intervention with modified ride on toy car, child showed improved mobility and vocalizations. |
- Study completed with 20-month-old with SMA: “Within 6 weeks after receiving the power wheelchair, the child operated the wheelchair independently. She showed developmental gains in all domains of the Battelle Developmental Inventory [communication, personal-social, and cognition] and the Pediatric Evaluation of Disability Inventory [positive trends in self-care, mobility, and social function] over 6 months” (p. 253). The authors conclude that the power mobility may have been associated with these changes. |
- During training period from age 7 months to 12 months, “the infant improved in all driving variables. The infant’s Bayley III cognition and language scores also increased at a rate greater than his chronological age” (p. 362). |

- “This study shows that although children may require extended trials and training to become proficient, power mobility can promote independence and development of young children with severe mobility impairments” (p. 139).
- In study, participants (as young as 14 months of age) had improvements in mobility, receptive communication, and self-care skills measured over a 12-month period.

**Early mobility and psychosocial development**

- Study included 23 children between the ages of 18 months and 6 years with various disabilities. Data collection occurred at “wheelchair evaluation, wheelchair delivery, and approximately 6 months later. Significant increases were found in parental perceptions of positive social skills for younger children after receiving a wheelchair; slightly older children showed improvements in social skills before the wheelchair was received; no changes were found in negative social skills” (p. 39).
- Social skills measures used: Adaptive Social Behavior Inventory (ASBI; Hogan, Scott, & Bauer, 1992) and the Preschool and Kindergarten Behavior Scales (PKBS; Merrell, 1994).

- Study completed with 20-month-old with SMA: “Within 6 weeks after receiving the power wheelchair, the child operated the wheelchair independently. She showed developmental gains in all domains of the Battelle Developmental Inventory [communication, personal-social, and cognition] and the Pediatric Evaluation of Disability Inventory [positive trends in self-care, mobility, and social function] over 6 months” (p. 253). The authors conclude that the power mobility may have been associated with these changes.

- Case study of 13-month-old over the course of 28 weeks.
- During intervention phase (12 weeks), daily car play sessions of 20-30 minutes with parents, with researcher visiting 1x/week to record 10-minute session. During retention phase, researcher visited 1x/week to record 10-minute session (no ROC outside of this visit).
- “Natalie's positive facial expressions increased in general from baseline through retention for each type of play. Natalie's positive facial expressions increased and decreased similarly during Car Play and Natural Play” (p. 421).
- “PEDI scores indicate that Natalie's performance of functional skills in self-care, mobility, and social function increased from pre- to postintervention” (p. 424).
Early mobility and self care

- Study completed with 20-month-old with SMA: “Within 6 weeks after receiving the power wheelchair, the child operated the wheelchair independently. She showed developmental gains in all domains of the Battelle Developmental Inventory [communication, personal-social, and cognition] and the Pediatric Evaluation of Disability Inventory [positive trends in self-care, mobility, and social function] over 6 months” (p. 253). The authors conclude that the power mobility may have been associated with these changes.

- “This study shows that although children may require extended trials and training to become proficient, power mobility can promote independence and development of young children with severe mobility impairments” (p. 139).
- In study, participants (as young as 14 months of age) had improvements in mobility, receptive communication, and self-care skills measured over a 12-month period.

- Case study of 13-month-old over the course of 28 weeks.
- During intervention phase (12 weeks), daily car play sessions of 20-30 minutes with parents, with researcher visiting 1x/week to record 10-minute session. During retention phase, researcher visited 1x/week to record 10-minute session (no ROC outside of this visit).
- “PEDI scores indicate that Natalie's performance of functional skills in self-care, mobility, and social function increased from pre-to postintervention” (p. 424).
Early mobility and visual perception

- Children who are independently mobile develop vision skills related to spatial relations directly through exploration of their environment. Children whose locomotion is limited to passive movements are in a state of “visual idle”.

Developmentally inspired seating

The Explorer Mini is an ergonomic device with multiple weight bearing surfaces to help promote safe, stable upright postures. The intuitive design provides just the right amount of support enabling young children with mobility impairments opportunities to develop strength, endurance and postural control.

Use of saddle seat

- Looked at 6 children aged 2.5 – 7yrs old with CP to compare the effects of flat-bench versus saddle-bench seating on postural control and reaching motions.
- “The saddle bench allowed significantly better postural control” and “the data suggests that the saddle seat may help such children develop and maintain seated postural control and upper-extremity movement patterns.”

- “Evidence supports that children with CP should be fitted for wheelchairs that place them in a FSP (Functional sitting position, which includes; orientation in space of 0-15 degrees, a hip-belt, an AO (abduction orthosis), footrests, and a cut out tray, with the addition of a sloped forward seat of 0-15 degrees, to improve upper-extremity function. The exact seat angle and orientation in space within the 0-15 degrees range should be determined on an individual basis.”

Use of midline joystick

- 20 children with bilateral spastic cerebral palsy, 11 with diplegia, 9 with quadriplegia, and 14 typically developing children drove powered wheelchairs in both unilateral and bimanual conditions.
- Conclusion: results suggest that bimanual interface might be beneficial for promoting symmetrical postural alignment in some children with bilateral spastic CP.
“These case studies suggest that to promote understanding of simple cause-effect relationships for individuals functioning at an early developmental level, it may be more effective to have the individual drive a powered wheelchair, than to operate switch controlled toys or apparatus.”

“The activity provides visual and auditory sensations, kinesthetic and vestibular sensations, and from this total bodily experience arises alertness. The joystick is placed in front of the driver rather close to the body making it easy to touch or hit the joystick accidentally. When the caused effect engages the whole body and changes the position in space, the individual is stimulated to repeat the activity. The accidental activity slowly grows more conscious, leading to active manipulation of the joystick to cause the effect, motion.”

Minimal postural supports

Study to look at whether daily balance training can affect the development of postural adjustments in 20 healthy sitting infants assessed at 5-6, 7-8, and 9-10 months of age.

“Training consisted of toy presentation in the border zone of reaching-without-falling. Special attention was put on sideward and semi-backward reaches.”

“Daily balance training can accelerate the development of postural control. The effect occurred at both levels of the postulated postural CPG model, i.e. training facilitated selection of the most complete, direction-specific response pattern and it accelerated the development of response modulation.”

Compared 2 interventions for improving sitting postural control in CP.

Infants with delays were randomly assigned to receive a home program (1 time per week for 8 weeks; mean age_15.5 months) or a perceptual-motor intervention (2 times per week for 8 weeks; mean age_14.3 months).

“Perceptual-motor intervention sessions were more dynamic and variable than the home program sessions.”

“Infants in the perceptual-motor intervention group developed postural control toward the values in infants with typical development, as measured by the COP variables, to a greater degree than the infants in the home program group.”
### Independence through exploration

The Explorer Mini gives very young children with mobility impairments the opportunity to increase their independence through exploration. Its intentional design, approachable aesthetic and growth adjustability encourages self-initiated independent movement.

<tr>
<td>While this study included elementary to young adult aged individuals (and their caregivers), it does highlight potential barriers to successful power wheelchair use including lack of transportation making it difficult to use the device in a community setting, desire for a smaller chair for ease of maneuverability in the home setting, performance over varied terrains, and width of aisles in store settings. Results from this study may indicate a smaller/easily transportable chair may result in increased use of the device outside the school setting.</td>

<tr>
<td>“Common concerns expressed by parents related to the weight, storage, transportation and technological difficulties of using power mobility equipment and stress the importance of a good match between the device, the user and the environment” (p. 961).</td>
<td></td>
</tr>
<tr>
<td>While findings suggest self-initiated power-mobility has a positive impact on the family, parents expressed concern most over “weight” and “ease of adjusting” power mobility device. This may suggest a device that is lighter and easier to adjust than a traditional power wheelchair may further reduce parental stress and negative emotions surrounding powered mobility devices for children.</td>
